We investigate the data streams. The orthogonality allows each subcarrier to be transmitted over a number of subcarriers. The interference occurs, and thus preserving the orthogonality as an independent channel, as long as no ICI (Inter-carrier Interference) occurs. In order to recover the channel estimation in OFDM, techniques such as frequency domain equalization, time domain windowing, extended kalman filtering etc. can be used to minimize the ICI.

OFDM is a frequency division multiplexing technique used as a multi carrier modulation method. Because of high capacity transmission of OFDM, it has been applied to digital transmission system, the basic principle of OFDM is to split a high rate data-stream into multiple lower rate data streams that are transmitted simultaneously over a number of subcarriers. OFDM uses the spectrum much more efficiently by spacing the channels much closer. This is achieved by making all the carriers orthogonal to one another, preventing interference between the closely spaced carriers. The orthogonality of the carriers is no longer maintained, which results in inter-carrier interference component of the received signal to be expressed as the product of the transmitted signal and channel frequency response at the subcarrier. Thus, the transmitted signal can be recovered by estimating the channel response just at each subcarrier. DFT channel estimation technique improve the performance of least-square (LS) and minimum-mean-square-error (MMSE) channel estimation.

A dynamic estimation of channel is necessary before the demodulation of OFDM signals since the radio channel is frequency selective and time-varying for wideband mobile communication. A dynamic estimation of channel is necessary before the demodulation of OFDM signals since the radio channel is frequency selective and time-varying for wideband mobile communication system. The channel estimation can be performed by either inserting pilot tones into all of the subcarriers of OFDM symbols with a specific period or inserting pilot tones into each OFDM symbol. The first one, block type pilot channel estimation, has been developed under the assumption of slow fading channel. Even with decision feedback equalizer, this assumes that the channel transfer function is not changing very rapidly. The estimation of the channel for this block-type pilot arrangement can be based on Least Square (LS) or Minimum Mean-Square (MMSE). The MMSE estimate has been shown to give 10–15 dB gain in signal-to-noise ratio (SNR) for the same mean square error of channel estimation over LS estimate . In , a low-rank approximation is applied to linear MMSE by using the frequency correlation of the channel to eliminate the major drawback of MMSE, which is complexity. The later, the comb-type pilot channel estimation, has been introduced to satisfy the need for equalizing when the channel changes even in one OFDM block. The comb-type pilot channel estimation consists of algorithms to estimate the channel at pilot frequencies and to interpolate the channel. The estimation of the channel at the pilot frequencies for comb-type based channel estimation can be based on LS,MMSE or Least Mean-Square (LMS). MMSE has been shown to perform

**Review of DFT based channel estimation techniques in OFDM over multipath channel**

**Abstract:** Channel estimation is one of the most significant technologies in the orthogonal frequency division multiplexing(OFDM) system and its accuracy will influence the performance of the whole system directly. Among all kinds of channel estimation algorithms, the least square (LS) estimation and the linear minimum mean-squared error (LMMSE) estimation are the most classic ones. However, both the two estimator are not able to reach a compromise between accuracy and computational complexity. The discrete Fourier transform (DFT)-based channel estimation can get a better performance by a time domain processing.

**Keywords**—Orthogonal frequency division multiplexing (OFDM) Inter carrier interference (ICI), The least-square (LS) and minimum-mean-square-error (MMSE), Discrete furrier Transform (DFT)-Based Channel Estimation.

**I. INTRODUCTION**

OFDM is a frequency division multiplexing technique used as a multi carrier modulation method. Because of high capacity transmission of OFDM, it has been applied to digital transmission system, the basic principle of OFDM is to split a high rate data-stream into multiple lower rate data streams that are transmitted simultaneously over a number of subcarriers. OFDM uses the spectrum much more efficiently by spacing the channels much closer. This is achieved by making all the carriers orthogonal to one another, preventing interference between the closely spaced carriers. The orthogonality of the carriers is no longer maintained, which results in inter-carrier interference component of the received signal to be expressed as the product of the transmitted signal and channel frequency response at the subcarrier. Thus, the transmitted signal can be recovered by estimating the channel response just at each subcarrier. DFT channel estimation technique improve the performance of least-square (LS) and minimum-mean-square-error (MMSE) channel estimation.

**II. CHANNEL ESTIMATION TECHNIQUES**

A dynamic estimation of channel is necessary before the demodulation of OFDM signals since the radio channel is frequency selective and time-varying for wideband mobile communication. A dynamic estimation of channel is necessary before the demodulation of OFDM signals since the radio channel is frequency selective and time-varying for wideband mobile communication system. The channel estimation can be performed by either inserting pilot tones into all of the subcarriers of OFDM symbols with a specific period or inserting pilot tones into each OFDM symbol. The first one, block type pilot channel estimation, has been developed under the assumption of slow fading channel. Even with decision feedback equalizer, this assumes that the channel transfer function is not changing very rapidly. The estimation of the channel for this block-type pilot arrangement can be based on Least Square (LS) or Minimum Mean-Square (MMSE). The MMSE estimate has been shown to give 10–15 dB gain in signal-to-noise ratio (SNR) for the same mean square error of channel estimation over LS estimate . In , a low-rank approximation is applied to linear MMSE by using the frequency correlation of the channel to eliminate the major drawback of MMSE, which is complexity. The later, the comb-type pilot channel estimation, has been introduced to satisfy the need for equalizing when the channel changes even in one OFDM block. The comb-type pilot channel estimation consists of algorithms to estimate the channel at pilot frequencies and to interpolate the channel. The estimation of the channel at the pilot frequencies for comb-type based channel estimation can be based on LS, MMSE or Least Mean-Square (LMS). MMSE has been shown to perform...
much better than LS. Depending on the arrangement of pilots, three different types of pilot structures are considered: block type, comb type, and lattice type. A block type of pilot arrangement is depicted in Figure 1.1. In this type, OFDM symbols with pilots at all subcarriers (referred to as pilot symbols herein) are transmitted periodically for channel estimation. Using these pilots, a time-domain interpolation is performed to estimate the channel along the time axis. Let \( s_t \) denote the period of pilot symbols in time. In order to keep track of the time-varying channel characteristics, the pilot symbols must be placed as frequently as the coherence time is. As the coherence time is given in an inverse form of the Doppler frequency Doppler in the channel, the pilot symbol period must satisfy the following inequality:

\[
s_t \leq \frac{1}{f_{\text{Doppler}}} \tag{1.1}
\]

Since pilot tones are inserted into all subcarriers of pilot symbols with a period in time, the block-type pilot arrangement is suitable for frequency-selective channels. For the fast-fading channels, however, it might incur too much overhead to track the channel variation by reducing the pilot symbol period. Comb-type pilot arrangement is depicted in Figure 1.2. In this type, every OFDM symbol has pilot tones at the periodically-located subcarriers, which are used for a frequency-domain interpolation to estimate the channel along the frequency axis. Let \( s_f \) be the period of pilot tones in frequency. In order to keep track of the frequency-selective channel characteristics, the pilot symbols must be placed as frequently as coherent bandwidth is. As the coherence bandwidth is determined by an inverse of the maximum delay spread, symbol period must satisfy the following inequality:

\[
s_f \leq \frac{1}{\sigma_{\text{max}}} \tag{1.2}
\]

As opposed to the block-type pilot arrangement, the comb-type pilot arrangement is suitable for fast-fading channels, but not for frequency-selective channels.

Lattice-type pilot arrangement is depicted in Figure 1.3. In this type, pilot tones are inserted along both the time and frequency axes with given periods. The pilot tones scattered in both time and frequency axes facilitate time/frequency-domain interpolations for channel estimation. Let \( s_t \) and \( s_f \) denote the periods of pilot symbols in time and frequency, respectively. In order to keep track of the time-varying and frequency-selective channel characteristics, the pilot symbol arrangement must satisfy both Equations (1.1) and (1.2), such that:

\[
s_f \leq \frac{1}{\sigma_{\text{Doppler}}} \quad \text{and} \quad s_f \leq \frac{1}{\sigma_{\text{max}}}
\]

where \( f_{\text{Doppler}} \) and \( \sigma_{\text{max}} \) denote the Doppler spreading and maximum delay spread, respectively.
II. TRAINING SYMBOL-BASED CHANNEL ESTIMATION

Training symbols can be used for channel estimation, usually providing a good performance. However, their transmission efficiencies are reduced due to the required overhead of training symbols such as preamble or pilot tones that are transmitted in addition to data symbols. The least-square (LS) and minimum-mean-square-error (MMSE) techniques are widely used for channel estimation when training symbols are available.

III. DFT-BASED CHANNEL ESTIMATION

The DFT-based channel estimation technique has been derived to improve the performance of LS or MMSE channel estimation by eliminating the effect of noise outside the maximum channel delay. Let \( \hat{H}[k] \) denote the estimate of channel gain at the \( k \)th subcarrier, obtained by either LS or MMSE channel estimation method. Taking the IDFT of the channel estimate \( \{\hat{H}[k]\}_{k=0}^{N-1} \)

\[
IDFT \{\hat{H}[k]\} = h[n] + z[n] \quad \text{for} \quad n = 0, 1, \ldots, N-1
\]

(2.1)

where \( z[n] \) denotes the noise component in the time domain. Ignoring the coefficients \( \hat{H}[k] \) that contain the noise only, define the coefficients for the maximum channel delay \( L \) as

\[
\hat{h}_{DFT}[n] = \begin{cases} h[n] + z[n], & n = 0, 1, 2, \ldots, L-1 \\ 0, & \text{otherwise} \end{cases}
\]

(2.2)

Figure 2.1 shows a block diagram of DFT-based channel estimation, given the LS channel.

IV. CONCLUSIONS

In this paper we investigate the channel estimation in OFDM by various method. We compare the different channel estimation techniques. The DFT-based channel estimation technique has been derived to improve the performance of LS or MMSE channel estimation by eliminating the effect of noise outside the maximum channel delay. The further work can be done by extending the concept of channel estimation.
